Gender Specific Differences in Auditory Brain Stem Response in Young Patients with ADHD

Abstract

Objective: The auditory brainstem response (ABR) is often affected in neurodevelopmental disorders. The aim of this study was to investigate gender differences in ABR between young females and young males with ADHD, compared to control subjects.

Method: We studied 63 females with ADHD (mean 13.8 years), 26 female controls (mean 13.8 years), 48 males with ADHD (mean 13.1 years), and 20 male controls (mean 12.8 years). All patients were diagnosed according to the DSM-IV. An ABR consists of seven positive peaks (wave I–VII) 10 ms following a stimulus, recorded by electrodes on the mastoid processes of each ear and on the forehead.

Results: When analysing the ABRs of the female ADHD patients 3 traits were identified; TR6, TR14 and TR15. The higher value in TR6 (p=0.000064) is explained as an aberrant thalamus profile. In TR14 (p=0.00059) presence of 3500 Hz-frequencies in the region from superior olivary complex to thalamus. TR15 (p=0.0035) represents more aberrant curve profiles in the region of the lateral lemniscus. In the ABR of the male patients we found we 3 traits; TR4, TR5 and TR14. TR 4 (p=0.00105) is a lower correlation to a norm curve in inferior colliculus and thalamic area. TR5 (p=0.00027) identifies irregular curve profiles representing the nucleus cochlea. TR14 (p=0.00013) presence of 3500 Hz-frequencies in the region from superior olivary complex to thalamus.

Conclusion: Young females with ADHD exhibited a significantly different ABR in a region between cochlear nucleus and superior olivary complex and in the thalamic region. In the male ADHD group ABR aberrancies were found in the midbrain region and in the more peripheral part; nucleus cœleus. The only trait that was significantly different between the ADHD group and the control subjects, for both male and females, was TR14. These data indicate both gender specific aberrations in the ABR in ADHD subjects as well as specific differences between ADHD subjects and normal controls.

Introduction

Attention deficit hyperactivity disorder (ADHD) has been recognized as one of the most common neurodevelopmental disorders in childhood [1]. It is a heterogeneous condition with persistent symptoms of hyperactivity, inattention and impulsiveness which impair functioning in multiple settings [2, 3]. ADHD is a highly heritable disorder and twin studies have shown a heritability rate of approximately 80% [4]. The estimated worldwide prevalence of ADHD in children is around 5% [5]. The symptoms frequently persist into adulthood and are associated with functional limitations as well as psychiatric and somatic morbidity. ADHD is a considerable burden to the affected individual and to society [1, 6]. ADHD is affecting both sexes, with a male to female ratio approaching 1:1 [7] contrasting to previous studies showing a gender ratio (girl:boy) ranging from 1:3 to 1:16 [8]. Over the years research has been trying to find differences in symptoms to explain the gender differences in prevalence. It
has been proposed that girls with ADHD may be more likely to have the inattentive type of ADHD and may suffer more from internalizing symptoms and inattention while, boys on the other hand have more hyperactive and aggressive symptoms [9-12].

An ADHD diagnosis should be based on neurodevelopmental and clinical history [1, 2]. In addition, neuropsychological testing and rating scales are often used as a supplement. There is a great need for objective measures to improve the diagnostic accuracy and to guide clinical interventions. There are recent studies that have focused on trying to find objective neuropsychological testing methods for the diagnostics of ADHD [13-17].

Auditory brainstem response (ABR) was first described in 1971 [18] and refers to the particular kind of event related potential (ERP) where the stimulus is sound, in this case, in the shape of distinct clicks at given intervals. In ABR, electrodes are placed and calibrated to study the processes that occur in the basic auditory pathways, situated in the brainstem [19] (Figure 1). ABR reflects the subcortical neuronal electrical activity in the auditory pathway within 10 milliseconds (ms) after brief auditory stimuli.

The ABR wave-pattern provides information in terms of the latencies and amplitudes of these peaks. Analysis of the ABR wave patterns normally comprises measurements of inter-peak latencies as well as ratios of peak amplitudes [20, 21]. ABR is an objective method that does not require active patient participation and is considered an objective approach to investigate brainstem function. In addition, complex stimuli may reveal aberrations, which may not be assessed by standard audiological ABR procedures. Complex click stimuli (e.g. forward masking) were therefore used in the present study to increase the possibility of detecting variances in comparison with matched healthy children. The importance of using complex stimuli is also stated for autism spectrum disorder, ASD [22].

Several studies have shown that ABR is often affected in ASD [23-28] adults with ADHD [29, 30], schizophrenia [28, 31, 32] and bipolar disorders [33]. Possible ABR abnormalities in young patients with ADHD need more studies [34, 35].

We have previously presented a study on ABR in young females with ADHD where we found ABR traits specific for young females with ADHD compared to control subjects [14]. The aim of the present study is to investigate possible gender differences in ABR between young females and young males with ADHD, compared to control subjects.

Methods

Subjects

This study included a total of 63 females with ADHD (age mean 13.8 years, SD 2.5), 26 female control subjects (age mean 13.8 years, SD 2.7), 48 young males with ADHD (age mean 13.1 years, SD 1.8), and 20 male control subjects (age mean 12.8 years, SD 1.7). Patients and control subjects were in the age range of 7-17 years. The age difference between boys and girls were not statistically significant. All patients were instructed to not take any medication the day of the testing.

All patients were recruited from the Child and Adolescent Psychiatry outpatient department of Eslov and Lund, two cities in the south of Sweden. All patients were diagnosed according to the Diagnostic and Statistical Manual of Mental Disorders, 4th Edition (DSM-IV). The diagnoses were confirmed by the same senior psychiatrist. The control groups were recruited from schools in Lund and recruited subjects had no previous record of any psychiatric disorder. Patients with other concurrent psychiatric diagnoses were excluded to avoid comorbidity. Subjects with hearing impairment were excluded from the study.

Written informed consent was obtained from all the subjects and their parents/guardians. The study was approved by the regional ethics committee at the Lund University (Dnr: 2010-120).

Apparatus and stimulus

The evoked potentials were recorded using auditory brainstem response, ABR. The ABR consists of a sequence of seven positive peaks (wave I–VII) that normally occur within 10 ms following the onset of a stimulus recorded by surface electrodes on the mastoid processes of each ear and on the forehead. Waves I and II are produced by the auditory nerve, whereas the subsequent peaks are due to the combined electrical activity of nuclei at gradually higher levels of the ascending auditory pathway in the brainstem. Waves III and IV are believed to be generated in the cochlear nucleus and superior olivary complex (SOC), respectively, whereas wave V is thought to represent activity at the levels of lateral lemniscus and inferior colliculus [36, 37]. The measuring system used was SensoDetect® BERA (Brainstem Evoked Response Audiometry) A1000. The stimuli were presented via TDH-50P headphones with Model 51 cushions (Telephonics, Farmingdale, New York, USA). Presentations were made binaurally with the stimuli in phase over headphones.
In total, 4 sound stimuli were used. The sound stimuli included square-shaped click pulses, high frequency varied pulses, forward masking and backward masking stimuli. The click pulses were repeated until a total of 1024 accepted evoked potentials had been collected for each sound stimulus. Thus, each ABR waveform represents an average of the responses to 1024 stimulus presentations. TTL (transistor-transistor logic) trigger pulses coordinated the sweeps with the auditory stimuli. A TTL pulse is the signal which tells the ABR system to measure. With a correctly timed TTL pulse, all ABR representations will be synchronized. Aberrant activity, such as extremely high amplitudes due to extraordinary movements was rejected. Sound levels were calibrated using a Bruel and Kjaer sound level meter and Type 4152 artificial ear (Bruel & Kjaer 5 & V Measurement, Naerum, Denmark). The acoustic output from the earphones corresponded to SPL: 80 dB HL or 109 peSPL (peak equivalence). A square-shaped click pulse was used as probe in the auditory masking stimuli [32]. The sound stimuli included square-shaped click pulses (0.136 ms duration, including 0.023 ms rise and fall; 192 ms interstimulus interval), high pass filtered pulses (a Butterworth high-pass filtered square shaped click pulse with a cutoff of 3000Hz), forward masking (12.3 ms gap from masker to click pulse) and backward masking (12.3 ms from click pulse to the masker) stimuli as previously described. A 1500-Hz Butterworth low-pass filtered white noise, with 15 ms duration (including 0.4 ms rise and fall times) was used as masker for both forward and backward masking stimuli. All stimuli were constructed using MATLAB Signal Processing Toolbox (The MathWorks, Inc., Natick, Massachusetts, USA) and stored in a flash memory in the Sensodetect® BERA system.

Procedure

All tests were performed in a soundproof slightly darkened room. Participants were comfortably seated in an armchair with their legs on a small footstool to assure a resting position. Five surface electrodes were applied: two reference electrodes on the mastoid bone behind the left and right ear, respectively, and two active electrodes and one ground electrode placed on the forehead. To make sure a good transmission the sites were washed with disinfectant and abrasive paste was used to stick the electrodes. Absolute impedances and inter electrode impedances were measured before and after the experiments to verify that electrode contact was maintained (below 5000 Ω). Earphones were fitted to cover both ears. The subjects were instructed to turn off their cellular phones and relax with their eyes closed and were permitted to fall asleep. The test requires no active participation other than being subjected to sound stimulation. Before the test situation written information had been sent home to the subject’s parents or guardians as well as to the subject. On site of the test session, subjects were again verbally informed of the nature of the experiments. The click sounds were presented to the subjects beforehand to make them acquainted with stimuli. The subjects were tested one at a time and the duration of the testing procedure was approximately 30 minutes.

Data analysis

Prior to further analysis the audiogram was correlated to ABR data, from a group of healthy and normal hearing individuals, derived from a normative database to depict general audiogram quality. This is a standard operating procedure of this method in order to grant audiogram quality. A low correlation led to exclusion of the patient due to risk of erroneous measurement (e.g. loose electrodes or head phones). The Sensodetect system rejected all evoked potentials being of abnormally high voltage (i.e. aberrant activity), typically triggered by patient movement, coughing or tension. Collected evoked potentials for each sound stimulus from each individual was imported to Microsoft Excel (Microsoft Corp, Redmond, WA, USA) and analyzed using Sensodetect® BAS. Frequencies, latencies, amplitudes and correlation coefficients to a normed ABR curve, respectively, were investigated. Amplitudes were measured from the positive peak of a given wave to the bottom of the previous wave. Since the amplitude values obtained were not read in µV, microvolt outputs were indexed (i.e., normalized by adding constants to avoid negative values, then all amplitude values were divided by the highest observed amplitude). Thus, relative linear amplitudes are used in this study. In order to identify specific pathologies along the auditory pathway, correlation values to a normative ABR curve were calculated for different sections of the ABR. Values ranging from -1 to +1 were obtained using Spearman rho. High, positive values indicate similarity (e.g. no pathology) values around zero indicate no relation, and low values close to -1 indicate inverse relationship. After the r-values for all sections of the total ABR curve (0-10 ms) had been computed, the results were ranked. Thus, the test subject’s most aberrant ABR region, when compared with the norm curve, depicts a high number, and vice versa (Figure 2).

The same principle was used in order to identify occurrence of high frequencies in the ABR curves of the test subjects. A mathematically constructed artificial ABR (a sine wave with the frequency 3500 Hz) was used as norm. Norm population median values for every data point in the ABR were used to construct the artificial ABR. Every patient’s ABR curve was correlated to this artificial ABR. The correlation value was calculated for each possible starting point in the ABR and the r (max) was used to indicate occurrence of the specific frequency. As the ambition with this operation was to see whether the test person had an occurrence of the frequency or not, the outcomes were ranked.

Figure 2 Median Curves of all Healthy females, ADHD females, Healthy males and ADHD females. Sound 1, left ears.
from 1 for all values between r=-1 to r=+0.1 and thereafter 2 for r=0.1 to r=0.2 and so forth, with 10 for r=0.9 to r=1, indicating a perfect match to the normed ABR.

Abercances in the ABR were denoted traits (TR). The ABR trait numbering emanated from the fact that a higher number of potentially interesting traits were originally investigated. However, not all of these qualified in terms of test-retest prediction values. Thus, the traits presented in this study shows gaps in numbering.

For measuring differences between young women with ADHD compared to age matched control group and young females with ADHD compared to age matched control group, the nonparametric test Mann–Whitney U was used.

**Results**

When analysing the ABRs of the female ADHD patients we found aberrances in three wave areas these included wave VI (i.e. denoted TR6: Aberrant thalamus profile ranging from 6.0-7.0ms), wave IV-VI (i.e. denoted TR14: Presence of 3500 Hz-frequencies in the region 4.0-7.5ms ranging from SOC to thalamus) and waves III-IV (i.e. denoted TR15: Aberrant profile in the region 3.3-4.3ms ranging from cochlear nuclei to SOC). In the ABR of the male patients we found aberrances in three areas; wave IV-VI (i.e denoted TR4: Low correlation to norm curve in the region 3.5-7.5 ms ranging from inferior colliculus to thalamus and i.e denoted TR14: Presence of 3500 Hz-frequencies in the region 4.0-7.5ms ranging from SOC to thalamus) and wave III (i.e denoted TR5: Low backward masking correlation to norm curve in the region 2.5-4 ms indicating a peripheral function deficit in the early auditory pathway.

Comparing the ABR of 63 girls with ADHD to 26 age correlated control subjects three traits were identified, denoted TR6, TR14 and TR15 (Figure 3a-e).

The higher value in TR6, specific for the ADHD females (p=0.000064), as compared with the female controls, is explained by more aberrant curve profiles in the thalamic region at 6.0-7.0 ms. In TR14, a higher presence of 3500 Hz-frequencies in the midbrain region at 4.0-7.5 ms (ranging from SOC to thalamus), was observed for the ADHD group as compared with controls (p=0.00059). The higher value in TR15, specific for the ADHD females at 3.3-4.3 ms (p=0.00035), as compared with the female controls, is explained by more aberrant curve profiles in the region of the lateral leminiscus (Table 1).

When looking at the ABR from 48 young males with ADHD and comparing them to their 20 age correlated control subjects we found three traits; TR4, TR5 and TR14 (Figure 3a-e). TR4 is described as a lower correlation to a norm curve in inferior colliculus and thalamic area at 3.5-7.5 ms (p=0.00105). TR 5 identifies irregular curve profiles within peak III, ranging from at 2.5-4.0 ms, representing the cochlear nucleus (p=0.00027). TR14 is described as a higher presence of 3500 Hz-frequencies in the region at 4.0-7.5ms (ranged from SOC to thalamus), was observed for the ADHD male group as compared with controls (p=0.00013).

The only trait that was significantly different between the ADHD group and the control subjects, for both male and females, was TR14 (Table 1).

**Discussion**

Due to the major rise in reported ADHD prevalence during the past decades [38], the public debate concerning the need for more objective ADHD diagnosis has been vivid [19, 39, 40]. We have recently published an article with results showing specific ABR differences in the young female group with ADHD compared to healthy controls [14].

The aim of this study was to identify differences in brainstem responses, ABR, in young patients diagnosed with ADHD.

compared to a control group. To our knowledge this is the first ABR study done on young patients (7-18 years) with ADHD trying to find gender specific ABR differences. In this study we compared the young females with ADHD both to a young female control group but also to young males with ADHD and their male control group. In the group of young males with ADHD we found three traits specific for ADHD compared to healthy controls; TR4, TR5 and TR14. In the young female group we found three traits not present in the healthy controls; TR6, TR14 and TR15. One trait co-occurred in both gender groups; TR14.

Looking at the ABR findings from a biological view, two of the female traits (TR6 and TR14) and one of the male traits (TR4) were found in the thalamic area or in the near proximity. This supports other studies that have shown structural and functional abnormalities in the deep parts of the brain of young patients with ADHD [41-43]. It has been described earlier that thalamic dysfunction leads to symptoms of hyperactivity, inattention and dysregulation of sleep and wakefulness all of which are symptoms of ADHD [44, 45]. The only trait that is not in the thalamic area is TR5 representing the cochlear nucleus, a more peripheral part of the brain. The cochlear nucleus is where parts of the auditory temporal processing occurs. It is an important component in sound detection in noisy environments and in selective auditory attention [46], deficits in these aspects of sound processing are frequent symptoms in ADHD.

TR15, only present in the young female ADHD group is located in lateral leminiscus; pons area. Previous studies regarding brain activity have shown higher resting-state activity in young patients with ADHD compared to controls in this area [47].

TR14 which is present in both gender groups is located in the midbrain ranging from SOC that is the first major site of convergence of auditory information from both ears important for localization of sound to thalamus. In Thalamus, transformation of soundsource acoustics (frequency, time and amplitude) into perceptual features (i.e. acoustic features) begins to form [48].

It is possible that these different traits found represent different subgroups of ADHD. Further research areas would be to link the person with a specific ABR trait to its reported symptoms. For example do patients with prominent TR5 report more ADHD symptoms involving hearing and sound detection?

Early studies have shown age and gender differences in ABR [49], whereas there are other more modern studies that demonstrate that the aging process is essentially a peripheral phenomenon which does not involve the central part of the acoustic pathways [50-52]. Neurodevelopmental differences may, at least partially, explain why girls are diagnosed so much later than boys [53]. Since our patients are age matched we believe that we have fully controlled for this factor in our study.

It is clear from our material that ABR in young patients with ADHD is gender specific. Only one trait namely TR14 overlapped; the others are gender specific.

**Table 1:** ABR results for young patients with ADHD compared to controls. Mann-Whitney U test was used. Female ADHD group (N=63), female controls (N=26), male ADHD group (N=48) and male controls (N=20).
Our findings support the fact that ADHD needs to be looked upon as a diagnosis composed of subgroups [9-12, 54, 55] a view that DSM5 and its subgrouping of ADHD supports. Our study shows that ABR has the potential to be the objective diagnostic instrument child and adolescent psychiatry has been looking for. ABR is a non-invasive method that is easily administered to patients; it is not dependent on language skills or cultural background [19]. Our findings suggest that ABR could be used as a complement and a support when diagnosing young patients with ADHD. By means of our ABR findings we have got a deeper understanding of the biological nature of ADHD and its subgroups. The present study suggests that the ABR method might provide useful biomarkers to support the clinical diagnoses of ADHD.

Many reports show possible regulation of locus coeruleus activity by methylphenidates and by atomoxetine [56-59]. Future research areas of interest would be to investigate whether medication would decrease the ABR differences between the group of children with ADHD and healthy controls, and if it is possible to predict choice of medical treatment according to trait match. There is also a need for longitudinal studies with child and adolescent control subjects with other psychiatric diagnoses to further substantiate our findings. We have therefor recently initiated a study of ABR and ASD in young patients. Another study regarding ABR and OCD has started in the autumn of 2015 at the University of Lund. Findings from these studies will be of great interest to investigate possible overlap with ADHD traits and the possible role of comorbidity.
