Abstract

In T cells PKC0 mediates the activation of critical signals downstream of TCR/CD28 stimulation. We investigated the molecular mechanisms by which PKC0 regulates NFκB transactivation by examining PKC0/β single and double knockout mice and observed a redundant involvement of PKC0 and PKCβ in this signaling pathway. Mechanistically, we define a PKC0-CYLD protein complex and an interaction between the positive PKC0/β and the negative CYLD signaling pathways that both converge at the level of TAK1/IKK/IκBζ/NFκB and NFAT transactivation. In Jurkat leukemic T cells, CYLD is endoproteolytically processed in the initial minutes of stimulation by the paracaspase MALT1 in a PKC-dependent fashion, which is required for robust IL-2 transcription. However, in primary T cells, CYLD processing occurs with different kinetics and an altered dependence on PKC. The formation of a direct PKC0/CYLD complex appears to regulate the short-term spatial distribution of CYLD, subsequently affecting NFκB and NFAT repressional activity of CYLD prior to its MALT1-dependent inactivation. Taken together, our study establishes CYLD as a new and critical PKC0 interactor in T cells and reveals that antagonistic PKC0/β-CYLD crosstalk is crucial for the adjustment of immune thresholds in primary mouse CD3⁺ T cells.

Introduction

The central role of PKC0 in signal transduction pathways during an adaptive immune response has extensively focused on the exact biochemical mechanisms of PKC0 function (reviewed in [1–3]). A recent study by Kong et al. identified the structural requirement in PKC0 for its localization to the immunological synapse as a prerequisite for activation of downstream signaling [4]. Several transcription factors essential for the T cell activation response (i.e. NFκB, AP1, and NFAT) are regulated by PKC0 [5,6]. In vivo analysis of PKC0−/− mice revealed the importance of PKC0 for Th2- [7] and Th17-mediated immune responses [8,9] but not for host-protective antiviral responses [10]. Nevertheless, despite a profound understanding of the cellular role of PKC0, little is known about its molecular function, specifically the effector proteins downstream of PKC0 during T cell activation.

Ubiquitylation and deubiquitylation are established posttranslational mechanisms for regulating immune responses, as well as the development and activation of immune cells. The tumor suppressor gene CYLD encodes an evolutionary conserved and ubiquitously expressed protein of approximately 120 kDa and was originally discovered as gene mutated in familial cylindromatosis, an autosomal dominant inherited disease characterized by the development of multiple benign skin tumors, principally on the head and neck [11]. Functionally it is a deubiquitylating enzyme (DUB) which removes mainly K63-linked polyubiquitin chains from several specific substrates, influencing in a negative way the activation status and/or spatial distribution of these target proteins in different signaling pathways. Numerous studies both in vitro and in vivo provided us with new insights in its established function as an important negative regulator of inflammatory responses, by counteracting the aberrant activation of NFκB signaling: Cyld−/− animals spontaneously develop intestinal inflammation and autoimmune symptoms due to the constitutive activation of the TAK1/IKK/IκBζ axis [12,13]; the study of Lim et al. described a CYLD dependent negative NFκB regulation during bacteria induced lung inflammation in mice via deubiquitylation of TRAF6 and TRAF7 [14]; moreover, the same scientific group showed that Cyld knockout mice are protected from Streptococcus pneumonia infection and lethality via a negative crosstalk with p38 MAPK [15]; a synergistic crosstalk between the E3 ligase Itch and CYLD for TAK1 inactivation and termination of tumor necrose factor dependent inflammatory signaling was recently described [16].
Figure 1. Overlapping roles of PKC\(\alpha\) and PKC\(\beta\) in NF\(\kappa\)B and NFAT transactivation processes in primary mouse CD3\(^+\) T cells. (A) PKC\(\beta\) expression is upregulated in whole cell extracts of peripheral CD3\(^+\) T cells derived from PKC\(\alpha\)-deficient mice. (B) The PKC isoform expression profile in whole cell extracts of naive thymocytes (Thy) and peripheral CD3\(^+\) T cells derived from wild-type and PKC\(\alpha\)/\(\beta\) double knockout mice. PKC\(\alpha\)/\(\beta\) inhibition leads to an
increased NF-κB and NFAT transactivation defect in T cells. (C) The nuclear extracts of resting and stimulated (overnight) wild-type, PKCδ−−, PKCβ−− and PKCβ−−/− CD3⁺ T cells were probed for DNA binding to radio-labeled probes containing NFκB and NFAT binding site sequences, as indicated. One representative experiment of three is shown. (D) Impaired nuclear import of p50, p65 and NFAT in activated PKCβ−−/− CD3⁺ T cells were probed for p65, p50 and NFAT using immunoblot assays. DNA polymerase served as the loading control. One representative experiment of three is shown. (E) Effect of PKCδ inhibition on proximal phosphorylation events after a brief stimulation. Western blot analysis was performed with cytosolic extracts from wild-type, PKCδ−−, PKCβ−−/− and PKCβ−−/− CD3⁺ T cells. CD3⁺ T cells were stimulated with anti-CD3/anti-CD28 and probed at different time points for the phosphorylation status of (p)S-32 IκBα, (p)S-473 AKT and (p)ERK1/2, as indicated. Fyn served as loading control. One representative experiment of three is shown. Protein phosphorylation levels were relatively quantitated by densitometric analysis. Numbers beneath bands indicate fold change compared to wt control after normalization to FYN.

doi:10.1371/journal.pone.0053709.g001

CYLD plays also an essential role in regulating T cell development and activation. Cyld-deficient mice show a delayed thymocyte development due to a constitutively K48-ubiquitylated and degraded LCK protein [17]. In addition, Cyld-deficient T cells are hyperresponsive to TCR/CD28 stimulation and CYLD has been firmly established as negative regulator of NFκB and JNK activation in response to antigen receptor activation in T cells [12,13,18].

In the current study, we defined physiologically redundant roles for the PKCδ and PKCβ isoforms in TCR/CD28-dependent NFκB and NFAT transactivation by examining PKCδ−− and double knockout mouse lines. Additionally, we provide experimental evidence that a constitutive interaction of PKCδ with CYLD apparently leads to CYLD sequestration that affects the transactivation of the critical transcription factors NFκB and NFAT. Therefore, the results described here elucidate some aspects of PKCδ and PKCβ function during TCR activation and the processes that modulate CYLD function upstream of NFκB and NFAT activation in primary CD3⁺ T lymphocytes.

Materials and Methods

Mice

PKCδ−−/− knockout mice are viable, fertile and were generated by crossing PKCδ−− [5] and PKCβ−− [19] single knockout mice. The generation of Cyld-deficient mice was described previously [20]. All mice were on a C57BL/6 background and housed (under SPF conditions) at the mouse facility at the Medical University of Innsbruck. All animal experiments were performed in accordance with the Austrian “Tierversuchsgesetz” (GBGL, Nr. 501/1988 i.d.g.F.) and have been granted by the Bundesministerium für Bildung, Wissenschaft und Kultur (bmwkw).

Plasmids and Reagents

Strep-HA-tagged PKCδ and Cyld cDNAs (full-length and R324A mutant) were cloned into pEF-Neo. Vectors expressing full-length Flag-tagged wild-type CYLD or N- or C-terminally truncated forms of CYLD (encoding residues 1–212, 318–956 and 587–986 of CYLD) were described previously [21].

The pan-PKC low molecular weight inhibitor LMW [22] was provided by NYCOMED GmbH, and the tetrapeptide inhibitor z-VRPR-Imk (MALT1 LMW) was a gift from Dr. Margot Thome.

Cell Culture and Transfections

Jurkat-TAg cells [23] (a kind gift from G.R. Crabtree, Stanford University, CA) were maintained in RPMI medium supplemented with 10% FCS (Life Technologies, Inc.) and antibiotics. Transient transfection of cells with 20 μg of plasmids encoding GFP, wild-type Cyld or a cleavage-resistant R324A Cyld mutant was performed by electroporation with a BTX-T820 Electro Square Porator (ITC, Biotech, Heidelberg, Germany) apparatus under predetermined optimal conditions: 2×10⁷ cells at 450 V/cm and five pulses of 90 ms.

HEK293T cells were cultured in Dulbecco’s Modified Eagle’s Medium supplemented with 10% FCS, 2 mM L-glutamine, and 100 μg/ml penicillin-streptomycin. HEK293T cells were transfected using Metafectene™ transfection reagent according to the manufacturer instructions.

Primary human T cells were purified from PBMCs (isolated by standard Hypaque–Ficoll separation from whole blood samples) with the Pan T Cell Isolation Kit (Miltenyi Biotec) according to the manufacturer instructions.

Primary mouse CD3⁺ T cells were purified from pooled spleens and lymph nodes with mouse T cell enrichment columns (R&D Systems). T cell populations were typically 95% CD3⁺ as determined by staining and flow cytometry.
Analysis of Proliferative Response and IL-2 Cytokine Production

For in vitro proliferation, $5 \times 10^5$ T cells in 200 µl proliferation medium (RPMI supplemented with 10% FCS, 2 mM L-glutamine and 50 units/ml penicillin/streptomycin) were added in duplicate to 96-well plates precoated with anti-CD3 antibody (clone 2C11, 5 µg/ml) and soluble anti-CD28 (1 µg/ml; BD Bioscience) was added. For TCR-independent T cell stimulation, 10 ng/ml Phorbol 12,13-dibutyrate (PDBu) and 125 ng/ml of the calcium ionophore ionomycin were added to the media. Cells were harvested on filters after a 64 h stimulation period, pulsed with H$^3$-thymidine (1 µCi/well) in the final 16 h and the incorporation of H$^3$-thymidine was measured with a Matrix 96 direct counter system.

For short time stimulation, cells were activated by the addition of anti-CD3 and anti-CD28 (or PDBu and ionomycin), both in soluble form. For crosslinking, anti-hamster IgG1 (clone HIG-632) was used.

IL-2 production in mouse CD3$^+$ T cells after antibody stimulation was determined by BioPlex technology (BioRad Laboratories) from the supernatant.

Western Blot Analysis

Cells were lysed in ice-cold lysis buffer [5 mM Na$_2$VO$_4$, 5 mM Na$_3$P$_2$P, 5 mM NaF, 5 mM EDTA, 150 mM NaCl, 50 mM Tris (pH 7.3), 2% NP-40, 50 µg/ml aprotinin and leupeptin] and centrifuged at 15,000 × g for 15 min at 4°C. Protein lysates were subjected to immunoblotting using antibodies against NFATc1 (Affinity Bioreagents), (p)S473 AKT, (p)ERK, ERK, (p)T183/
Figure 3. T cells from Cyld−/− mice exhibit hyper-responsiveness to TCR stimulation. (A) Naive wild-type and Cyld deficient CD3+ cells were stimulated overnight (16 h) with the indicated amount of plate-bound anti-CD3 and soluble anti-CD28. Cytokines in the supernatants were measured using Bioplex suspension array technology. (B) Nuclear extracts were isolated from unstimulated and CD3/CD28-stimulated CD3+ T cells from wild-type control and Cyld−/− mice. EMSA was performed to determine the activity of NFAT and NFκB. The same nuclear extracts were probed for NFAT and DNA polymerase, using immunoblot assays, the latter one served as the loading control. (C) Purified naive peripheral CD3+ T cells from wild-type and Cyld−/− mice were stimulated with anti-CD3 and anti-CD28 for the indicated time periods. Immunoblotting assays were performed using the
Y185 JNK, JNK, p50, p65, (p)Y-783 PLCγ1, (p)T184/187Tak1, Tak1 (all from Cell Signaling), PKCβ, PKCθ (both from BD Transduction Laboratories), actin, Cyld (E10), DNA polymerase and Fyn (all from Santa Cruz Biotechnology). The Cyld antibody recognizing the NH2-terminal region of Cyld was described previously [20].

Co-immunoprecipitation Analysis

For co-immunoprecipitation, 1 × 10⁷ primary mouse T cells (or 1 × 10⁶ transiently transfected HEK293T cells) were lysed in 400 μl of immunoprecipitation buffer [5 mM Na₂VO₄, 5 mM NaP₂P, 5 mM NaF, 5 mM EDTA, 150 mM NaCl, 1% NP-40, 50 mM Tris [pH 7.4], 50 mg/ml aprotonin and leupeptin]. Lysates were precleared for 1 h at 4°C. Immunoprecipitation was performed at 4°C overnight using 2 μg of the relevant antibodies. Thereafter, lysates were incubated with protein G Sepharose (Amersham-Pharmacia, Vienna) [for Streptactin IP, Streptactin Beads were used] for 1 h at 4°C, extensively washed in lysis buffer, resolved on an SDS-PAGE and immunostained for the relevant protein.

Gel Mobility Shift Assays

Nuclear extracts were harvested from 1 × 10⁷ cells according to standard protocols. Briefly, purified CD3⁺ T cells were washed in PBS and resuspended in 10 mM HEPES (pH 7.9) 10 mM KCl, 0.1 mM EDTA, 0.1 mM EGTA, 1 mM DTT and protease inhibitors. Cells were incubated on ice for 15 min. NP-40 was added to a final concentration of 0.6%, cells were vortexed vigorously, and the mixture was centrifuged for 5 min. The nuclear pellets were washed twice and resuspended in 20 mM HEPES (pH 7.9), 0.4 M NaCl, 1 mM EDTA, 1 mM EGTA, and 1 mM DTT and protease inhibitors, and the tube was rocked for 30 min at 4°C. After centrifugation for 10 min, the supernatant was collected. Extracted proteins (2 μg) were incubated in binding buffer with [32P]labeled, double-stranded oligonucleotide probes (NFκB: 5’-GCC ATG GGG GGA TCC CCG AAC TCC-3’; NFAT: 5’-GCC CAA AGA AGA AAA TTT GTT TGG TAG AG-3’ (Nushift; Active Motif)). In each reaction, 3 × 10⁷ c.p.m. of labeled probe was used, and the band shifts were resolved on 5% polyacrylamide gels. All experiments were performed at least three times with similar outcomes.

Flow Cytometry

Single-cell suspensions from the spleen, lymph node and thymus were prepared and incubated for 30 min on ice in staining buffer (PBS containing 2% fetal calf serum and 0.2% NaN₃ with FITC, PE or APC antibody conjugates. Surface marker expression was CD44, and CD25 were obtained from BD PharMingen. CD8 were obtained from Caltag Laboratories; CD19, CD69, (p)Y-783 PLCγ1, (p)T184/187Tak1, Tak1 (all from Cell Signaling), PKCβ, PKCθ (both from BD Transduction Laboratories), actin, Cyld (E10), DNA polymerase and Fyn (all from Santa Cruz Biotechnology). The Cyld antibody recognizing the NH2-terminal region of Cyld was described previously [20].

Retroviral Transduction of Primary Mouse T cells

The packaging cell line p tat E was transfected with a pMX retroviral vector encoding an EGFP-CYLD fusion cDNA. Approximately 36 h later, supernatants were collected and used directly to infect 24 h to 48 h preactivated CD3⁺ cells using spin inoculation (1 h, 2000 g, 32°C), followed by a 5-6 h incubation period at 37°C. Infected cells were washed, resuspended in full supplemented medium and incubated for an additional 48 h to 72 h. From these cultures, GFP-expressing cells were analyzed using confocal microscopy to track the subcellular distribution of the protein of interest.

Monitoring CYLD Localization Using Confocal Microscopy

CD3⁺ cells from wild type and PKCθ/β knockout mice that were transduced with a retrovirus expressing an EGFP-CYLD were not stimulated or PDBu- and ionomycin-stimulated, transferred to a polylysine-coated slide and fixed with 2% paraformaldehyde. After permeabilization (0.1% TritonX-100 in PBS) and a blocking step (5% goat serum in PBS), the cells were stained with Alexa595-CTB (for lipid raft staining) and TOPRO 3 (Nucleus) (Molecular Probes). Immunofluorescence was analyzed with a Zeiss LSM 510 confocal laser scanning microscope and Zeiss LSM software v3.2.

Statistical Analysis

Differences between genotypes were analyzed using the unpaired Student’s t test.

Results

Overlapping Roles of PKCθ and PKCβ in NFκB and NFAT Transactivation Processes in Primary Mouse CD3⁺ T cells

Studies using targeted gene disruption defined a critical role for PKCθ in the activation of the IL-2 promoter in the NFκB and Ca²⁺/NFAT pathways [5,6]. Surprisingly, the phenotypic characterization of PKCθ-deficient T cells revealed a strong upregulation of PKCθ protein levels in PKCθ single knockout T cells (Fig. 1A). To investigate potentially compensatory and overlapping roles of these two PKC family members in T cell activation processes, PKCθ/β double knockout mice were generated. These mice were viable, fertile and bred at normal Mendelian ratios. The null mutations for PKCθ and PKCβ were confirmed by PCR and immunoblotting of whole cell lysates from naive thymocytes and peripheral CD3⁺ T cells (Fig. 1B).

Flow cytometric analysis of thymocyte populations in PKCθ/β−/- double knockout mice revealed a slightly diminished percentage of CD3-, CD4- and CD8-positive cells, comparable to the PKCθ single knockout phenotype and in agreement with previous research [24,25], which might indicate an involvement of PKCθ in the positive selection process during thymocyte development. Nevertheless, in the periphery, PKCθ/β−/- mice revealed no gross differences in the distribution of CD3-, CD4-, CD8-positive cells, leading to the conclusion that the concomitant loss of PKCθ and PKCβ did not additively affect T cell development (Table 1+ Table 2).

Examination of the stimulation-dependent upregulation of CD25, CD69 and CD44 surface markers on CD4⁺ and CD8⁺ subsets revealed no gross differences in the total percentage of positive cells between the genotypes, but the total protein amount per cell, monitored by median fluorescence intensity, was strongly reduced in PKCθ/β−/- and to an intermediate extend in PKC singly-deficient T cells. These data might indicate a possible defect in the upregulation of both the IL-2 receptor chain alpha (CD25) and the activation marker CD69 in PKCθ-deficient T cells in both CD4⁺ and CD8⁺ T cells (Fig. S1).
In contrast to the relatively normal T-cell development observed, the T-cell response of peripheral T cells after TCR stimulation was affected by the single and simultaneous loss of PKCω and PKCβ. The H2-thymidine uptake and IL-2 secretion response of PKCω/β-deficient T cells stimulated with anti-CD3 and with or without anti-CD28-activated did not significantly exacerbate the defects already observed in the absence of PKCω alone (Fig. S2A-C). To exclude the proliferative defects being caused by deregulated apoptosis, we analyzed the activation-induced cell death (AICD) of CD4+ and CD8+ T-cell blasts derived from wild-type and double knockout animals using CD3 engagement in vitro; in addition also the Fas ligand induced cell death was monitored, but no enhanced apoptotic responses of PKCω/β were detected (Fig. S3A–B).

However, analysis of the pathways leading to IL-2 transcription revealed additively reduced binding of NFκB and NFAT to DNA in PKCω/β double-deficient CD3+ T cells after CD3/CD28 stimulation (Fig. 1C). Immunoblot analysis of nuclear extracts demonstrated that the weaker DNA binding of NFκB and NFAT was due to the reduced nuclear entry of two NFκB subunits, p50 and p65, and NFAT upon stimulation (Fig. 1D). Activation of NFκB involves the phosphorylation of IκB by IKKβ and its subsequent proteasomal degradation. Consistent with the additive effect on NFκB translocation, the double knockout showed a weaker IκBα phosphorylation after stimulation with CD3/CD28. Also the activation of the Map kinase pathway was partially affected by PKCω/β deficiency, visible through a reduced ERK phosphorylation, whereas the activation of Akt/PKB was normal (Fig. 1E).

PKCω and PKCβ Synergistically Regulate TAK1 and JNK Activation

In agreement with the defective IKK/IκBα axis, PKCω/β−/− CD3+ cells revealed a drastic activation defect in TGF-β activated kinase 1 (TAK1), which is known to be a key regulator of IKKβ signaling. The loss of both PKC isoforms appears to be required to abolish the signal, because TAK1 activation levels were similar between the wild-type and PKC single knockout T cells (not shown). Additionally, the JNK signal was attenuated by the targeted disruption of PKCω and PKCβ, whereas ERK1/2 activation was only marginally affected (Fig. 2A). Similar outcomes were observed in PDBeu- and ionomycin-stimulated primary mouse wild-type T cells pretreated with 500 nM of a PKC-specific low molecular weight inhibitor (PKC LMWI). The stronger effect of the pharmacological pan-PKC inhibitor on MAP kinase activation can be best explained by its explained inhibition of additional PKC family members next to PKCω and PKCβ (Fig. 2B).

Cyld−/− T cells Show a Hyperactive Phenotype in NFκB and NFAT Transactivation Responses

Since the deubiquitinating enzyme CYLD has been shown to be a negative regulator of Taki [12] and JNK signaling [26], we investigated a possible link between CYLD and the PKCω/β isoforms in NFκB and NFAT driven IL-2 upregulation.

Despite of an observed thymocyte maturation defect, recent work on T cell signaling in Cyld−/− mice demonstrated hyper-responsiveness to TCR stimulation by constitutive activation of NFκB [12]. We confirmed these results, as we also observed that Cyld−/− T cells showed elevated activation-induced IL-2 responses (Fig. 3A). This hyper-responsive IL-2 secretion correlated with an increase of NFκB DNA binding to the IL-2 promoter in the nuclear fractions of stimulated Cyld−/− T cells (Fig. 3B) and hyper-phosphorylated IκBα levels in the cytosol compared to wild-type controls (Fig. 3C). Interestingly, and in accordance with a previous publication [27], we determined that CYLD also acts as a negative modulator of the NFAT pathway. The examination of NFAT transactivation using immunoblot and EMSA technology revealed increased nuclear translocation and subsequent binding of NFAT to DNA in Cyld-deficient cells (Fig. 3B). Our EMSA result was confirmed by the elevated activation status of phospholipase Cγ1, which has been identified as a key regulator of Ca2+/Calcineurin/NFAT signaling. However, ERK signaling was not affected by the loss of Cyld (Fig. 3C).

Association of CYLD with PKCω

Considering the reciprocal phenotypes of Cyld- and PKCω-deficient T cells involving NFAT and NFκB transactivation we investigated a potential direct interaction between these enzymes. Interestingly and indeed, we identified a physical and functional PKCω-CYLD interaction in the cytosol of primary T cells. The co-immunoprecipitation analysis of CYLD and the PKCω isotype from cell extracts of unstimulated and CD3/CD28-activated peripheral CD3+ cells revealed that PKCω and CYLD physically associate in a complex in resting conditions (Fig. 4A). Next, we mapped the PKCω interaction domain in the CYLD protein by co-transfection of HEK293T cells with a vector encoding PKCω and with vectors expressing full-length CYLD constructs together CYLD constructs into HEK293T cells. As previously, the importance of the C-terminal region of CYLD for binding is shown. GFP controls for each CYLD construct were included. One representative experiment of three is shown.

In Jurkat Cells, CYLD is Cleaved by MALT1 in a PKCω-dependent Mechanism

When Jurkat cells overexpressing an N-terminally HA-tagged CYLD construct were stimulated for 30 min with PDBeu and ionomycin, a CYLD fragment of approximately 40 kDa was observed. Additionally, the JNK signal was attenuated by the specific low molecular weight inhibitor (PKC LMWI). The stronger effect of the pharmacological pan-PKC inhibitor on MAP kinase activation can be best explained by its explained inhibition of additional PKC family members next to PKCω and PKCβ (Fig. 2B).

Cyld−/− T cells Show a Hyperactive Phenotype in NFκB and NFAT Transactivation Responses

Since the deubiquitinating enzyme CYLD has been shown to be a negative regulator of Taki [12] and JNK signaling [26], we investigated a possible link between CYLD and the PKCω/β isoforms in NFκB and NFAT driven IL-2 upregulation.

Despite of an observed thymocyte maturation defect, recent work on T cell signaling in Cyld−/− mice demonstrated hyper-responsiveness to TCR stimulation by constitutive activation of NFκB [12]. We confirmed these results, as we also observed that Cyld−/− T cells showed elevated activation-induced IL-2 responses (Fig. 3A). This hyper-responsive IL-2 secretion correlated with an increase of NFκB DNA binding to the IL-2 promoter in the nuclear fractions of stimulated Cyld−/− T cells (Fig. 3B) and hyper-phosphorylated IκBα levels in the cytosol compared to wild-type controls (Fig. 3C). Interestingly, and in accordance with a previous publication [27], we determined that CYLD also acts as a negative modulator of the NFAT pathway. The examination of NFAT transactivation using immunoblot and EMSA technology revealed increased nuclear translocation and subsequent binding of NFAT to DNA in Cyld-deficient cells (Fig. 3B). Our EMSA result was confirmed by the elevated activation status of phospholipase Cγ1, which has been identified as a key regulator of Ca2+/Calcineurin/NFAT signaling. However, ERK signaling was not affected by the loss of Cyld (Fig. 3C).

Association of CYLD with PKCω

Considering the reciprocal phenotypes of Cyld- and PKCω-deficient T cells involving NFAT and NFκB transactivation we investigated a potential direct interaction between these enzymes. Interestingly and indeed, we identified a physical and functional PKCω-CYLD interaction in the cytosol of primary T cells. The co-immunoprecipitation analysis of CYLD and the PKCω isotype from cell extracts of unstimulated and CD3/CD28-activated peripheral CD3+ cells revealed that PKCω and CYLD physically associate in a complex in resting conditions (Fig. 4A). Next, we mapped the PKCω interaction domain in the CYLD protein by co-transfection of HEK293T cells with a vector encoding PKCω and with vectors expressing full-length Flag-tagged wild-type CYLD, N- or C-terminally truncated forms of CYLD (residues 1–212, 318–956 and 587–986 of CYLD). Untransfected and GFP-transfected controls were included. One representative experiment of three is shown. A schematic representation depicts the CAP-Gly and peptidase domains in wild-type and truncation mutants of CYLD. (C) Co-immunoprecipitation of CYLD using PKCω pulldown. A strep-tagged full-length PKCω construct was co-transfected with Flag-tagged CYLD constructs into HEK293T cells. As previously, the importance of the C-terminal region of CYLD for binding is shown. GFP controls for each CYLD construct were included. One representative experiment of three is shown.

doi:10.1371/journal.pone.0053709.g004
Figure 5. CYLD is endoproteolytically processed in the Jurkat cell line and in primary human T cells. (A) The essential role of both the catalytic activity of PKC and MALT1 for activation-dependent CYLD cleavage. Jurkat cells transfected with HA-tagged Cyld vectors were activated by PDBu and ionomycin in the presence of PKC and MALT1 pharmacological inhibitors. After 20 min, cells were lysed and fractionated into membrane (m), cytosolic (c) and nonsoluble (ns) fractions. CYLD and its clipping product were present in (c), inhibition of PKC and MALT1 activity blocks CYLD cleavage. (B) CYLD processing occurred also under endogenous conditions in stimulated primary human T cells isolated from whole blood samples;
detected using the anti-HA antibody. Because the administration of PDBu mimics TCR signaling by activating PKC family members, we wanted to identify a role for PKC in this cleavage event. Therefore, Jurkat cells were pretreated with the specific pan-PKC pharmacological inhibitor, which resulted in the disappearance of this fragment (Fig. 5A). This finding emphasized that the endoproteolytic cleavage of CYLD is PKC dependent. We also isolated primary T cells from human whole blood and analyzed the CYLD processing under endogenous conditions. In addition, human T cells were treated with the pan-PKC inhibitor to investigate the PKC dependency in this process. Comparable to the results with Jurkat cells, CYLD underwent a stimulation dependent processing also in primary human T cells, which could be blocked by PKC inhibition. The generation of a 40 kDa NH2-terminal and a 70 kDa C-terminal cleavage fragment was confirmed via the use of NH2- and C-terminus recognizing specific CYLD antibodies (Fig. 5B).

Because Coornaert et al. showed that the paracaspase MALT1 directly cleaved the deubiquitinating protein A20 to generate a fragment with a smaller molecular size in stimulated T cells [28], we asked if MALT1 was also responsible for the cleavage of CYLD by treating Jurkat cells with the tetrapeptide inhibitor z-VRPR-fmk, which has been shown to inhibit specifically the MALT1 protease activity [29]. As a result, cells treated with the MALT1 inhibitor showed a reduced CYLD cleavage after activation (Fig. 5A).

Based on the size and the molecular weight of the CYLD N-terminal 40 kDa proteolytic fragment, we identified the cleavable arginine residue at position 324 in the human CYLD protein and generated a Cyld mutant with alanine substituted for arginine at position 324 (Cyld-R324A). Next, we investigated if this mutant was cleavable when overexpressed in Jurkat cells or was resistant to proteolysis. Wild-type CYLD was processed after stimulation, whereas the mutant could no longer be cleaved (Fig. 5C). This led to permanent inhibition of the NFκB pathway by the inactivation resistant CYLD mutant and result in slightly diminished phosphorylation of IκBα. The MAPK pathway was not affected by the expression of uncleavable CYLD.

Because NFκB is important for IL-2 upregulation in activated T cells, we tested the influence of the protease-resistant Cyld mutant on IL-2 transactivation using an IL-2-promoter-dependent luciferase assay. The diminished NFκB signal observed by immunoblot was correlated with impaired IL-2 transcription (Fig. 5D). This provides experimental evidence that CYLD processing, which leads to an inactivation of its repressor function within a positive feedback loop, is an important prerequisite for robust IL-2 activation. Consistent with our investigation of CYLD cleavage at arginine 324 in the Jurkat tumor cell line, Staal et al. independently published that TCR-induced JNK activation required CYLD proteolysis by MALT1 [18]. Nevertheless, our findings extend the function of CYLD cleavage to NFκB activation. To identify the physiological role of this candidate process, we examined primary CD3+ T cells derived from wild-type and knockout mice.

PKC-dependence, Cleavage Site and Kinetics of CYLD Cleavage Differ in Primary Mouse T cells

Stimulation induced a CYLD fragment not only in human cells but also in primary mouse T cells. Interestingly activation of primary mouse T cells by CD3 with or without CD28 costimulation generated a NH2-terminal CYLD fragment of approximately 25 kDa, smaller in size than the human fragment (Fig. 6A), implicating a different cleavage site in the mouse CYLD protein. Although we did not determine the exact cleavage site, arginine 235 was the best candidate for the cleavage site. Importantly, the fragment was first detectable after 4 h of stimulation, indicating different kinetics leading to CYLD inactivation in primary mouse cells. Unexpectedly, PKCα/β-deficient T cells showed normal CYLD processing after stimulation, implicating additional protein kinases in this process (Fig. 6B). As a consequence, the activation defects of the TAK1/IKK axis in PKCα/β-deficient T cells cannot solely be explained by CYLD inactivation.

Alternatively, the existence of a constitutive CYLD/PKCα complex might suggest that PKCα, which shows activation-dependent subcellular translocation, is important for removing CYLD from its NFκB-related targets and attenuates the negative regulatory function of CYLD, enabling feedback control of NFκB activation. To address this hypothesis, we analyzed the subcellular distribution of a retrovirally introduced mutant CYLD-GFP fusion protein in unstimulated and stimulated wild-type and PKCα/β-deficient T cells with confocal microscopy. CD3+ T cells from both genotypes were retrovirally infected with a CYLD-GFP fusion construct, and the colocalization of CYLD-GFP with lipid rafts was monitored with Cholera Toxin B. Interestingly, CYLD colocalization with lipid rafts was strongly diminished in PKCα/β-deficient T cells compared to control cells, suggesting PKC-dependent CYLD membrane shuttling. A statistically significant decrease in CYLD translocation in double knockout cells was detected in unstimulated cells, whereas after 15 min of PDBu and ionomycin stimulation, CYLD translocation to the membrane was observed in both wild-type and knockout cells (Fig. 6C).

Discussion

Numerous studies emphasize PKCα key role as a regulator of NFκB and Ca2+/NFAT signaling in T cells downstream of the TCR [5,6,30–32]. The PKCβ isotype is also expressed in T cells. However, PKCβ-deficient primary mouse T cells have a fairly normal activation response [33], although Volkov et al. established a major role for PKCβ in LFA1-dependent T-cell locomotion [34,35].

Our recent work defines a redundant role for both the novel PKCα variant and the classical isotype PKCβ in the NFκB and NFAT signaling pathways. T cells isolated from PKCα/β-deficient mice had a stronger impairment in NFκB and NFAT nuclear entry and DNA binding compared to CD3+ T cells from control and single knockout mice. Impaired TAK1 activation in double-deficient T lymphocytes is the best candidate for restricted IKK/IκBα signaling. Functional redundancy of PKC0 with other members of the PKC family in NFκB and/or NFAT activation has been shown in previous studies. For instance, stimulation-
Figure 6. CYLD cleavage in primary mouse T cells shows a different kinetic. (A) CYLD cleavage in primary mouse cells has different kinetics. The activation of primary mouse T cells by CD3 with or without CD28 costimulation leads to the formation of an NH2-terminal CYLD fragment of...
dependent colocalization of atypical PKCz/θ with PKCθ in the lipid raft fraction of T lymphocytes leads to cooperation of these isoforms in modulating the NFκB signaling pathway [36]. The collaborative activity of PKCθ and PKCz in the NFAT pathway was examined in a PKCz/θ double knockout mouse strain. Compared to PKCθ and PKCθ single-deficient T cells, double-deficient CD3ε cells showed additively reduced IL-2 secretion levels correlated with strongly impaired nuclear translocation and DNA binding of NFAT after stimulation. Of note, the PKCz/θ double knockout mice showed an impaired interleukin response, leading to significantly prolonged allograft survival in heart transplantation experiments [37].

Similar to phosphorylation, K63 ubiquitination is a reversible process that influences protein activity, trafficking and signaling complex assembly. The removal of ubiquitin chains is mediated by a family of deubiquitinas, of which the cylindromatous gene product CYLD and the Tumor necrosis factor α-induced protein 3, also called A20, is currently receiving broad scientific attention. Both CYLD and A20 have been implicated as a modulator of the activity of NFκB-related molecules, such as NEMO [IKKγ], TRAF2 and TRAF6 [38–40]. Both enzymes overlap functionally by targeting a similar set of substrates, which was explained by the different expression pattern of A20 and CYLD. A20 function depends on its transcriptional upregulation, whereas CYLD is constitutively expressed, influencing different time windows of NFκB activation differently. However, a constitutive expression and activity pattern requires a posttranslational regulatory mechanism to inactivate the repressor during signal-induced NFκB signaling.

The cleavage-dependent inactivation of a deubiquitinas as a posttranslational regulatory mechanism in activated T cells was first described by Coornaert et al. [28], in which A20 was defined as a deubiquitinase. The cylindromatous complex assembly. The removal of ubiquitin chains is mediated by a process that influences protein activity, trafficking and signaling
