KEY WORDS:

Primary Sjögren’s syndrome, lymphoma, cohort study, CD4+ T-lymphocytopenia,
predictors
ABSTRACT

Objectives: Assessing the risk of lymphoproliferative disease or other malignancy (Standardized Incidence Ratios (SIR)), in patients with primary Sjögren’s syndrome (pSS) according to the American-European Consensus Criteria (AECC), compared with patients with sicca-syndrome (non-AECC) and the background population. Identification of predictors of malignancy. Description of lymphoma types and survival probabilities.

Methods: Linked register study using information from the Malmö Primary SS Register combined with the Swedish Cancer Register and Cause-of-Death Register for calculation of SIRs. Re-classification of the detected lymphomas according to WHO classification. COX regression analysis to study the predictive value of clinical, laboratory and histological findings at the time of diagnosis.

Results: 507 patients (286 AECC-SS) with a median follow-up of 8 years (range 1 month up to 19 years) were included. SIRs (95% Confidence Interval (CI)) for malignancies in total and for non-Hodgkin’s lymphomas (NHL) were 1.42 (0.98-2.00) and 15.57 (7.77-27.85) respectively in those fulfilling the AECC (n=286). In non-AECC sicca patients (n=221) SIR for malignancy of any kind was 0.77 (0.41-1.32), no lymphoproliferative neoplasms were detected. Significant predictors of lymphoproliferative disease were purpura/skin vasculitis (Hazard Ratio (HR): 4.64, 95%CI: 1.13-16.45), low complement factor C3 (HR: 6.18, 95%CI: 1.57-24.22), low C4 (HR: 9.49, 95%CI: 1.94-46.54), CD4+ T-lymphocytopenia (HR: 8.14, 95%CI: 2.10-31.53) and a low CD4+/CD8+ T-cell ratio ≤0.8 (HR: 10.92, 95%CI: 2.80-41.83). 58 % of the NHLs were diffuse large B-cell lymphomas.

Conclusion: The present study reveals 16 fold increased risk for development of NHL. In addition to previously recognized predictors CD4+ T-lymphocytopenia is a strong risk factor for developing lymphoma.

INTRODUCTION

Primary Sjögren’s syndrome (pSS) is an autoimmune connective tissue disease with an estimated prevalence of 0.5% among adults, when classified according to the American-European Consensus Criteria (AECC)[1-3]. The aetiology is unclear. Genetic, hormonal, environmental (mainly infectious) and other factors (such as birth weight [4]) interact in its pathogenesis [5, 6].

Patients with pSS experience mouth and/or eye dryness as the main consequence of an autoimmune destruction or functional blockade of the exocrine gland tissue. The most frightening complication of pSS is lymphoproliferative malignancy. In 142 SS patients admitted to the National Institute of Health (NIH) between 1954 and 1975 seven lymphomas were observed and resulted in a relative risk of lymphoma of 44.4 for pSS [7]. Several studies have confirmed this association and a lifetime risk of around 5%-10% [8-11]. Malignant lymphoma is the only cause of death, for which pSS patients are at increased risk [11, 12]. Several predictors of lymphoma development have been identified. Clinical signs such as lymphadenopathy [10, 11, 13], swollen salivary glands [7, 10, 11, 13], palpable purpura or skin vasculitis [11, 14], peripheral nerve involvement [14], leg ulcers [13], low-grade fever [14], use of cytotoxic drugs [7], younger onset pSS [7, 9] and laboratory predictors such as anaemia [14], lymphopenia [14], low levels of C3 [12, 15] and C4 [11, 12, 15], and
cryoglobulinaemia [15, 16] have been described. Reports from our group [17, 18] and others [19-21] have drawn attention to the high frequency of CD4+ T-lymphocytopenia and its possible connection to lymphoma development. After 1976 [7] no studies have contributed with prospectively followed cohorts, high precision of assessment of the associated malignancies and comparison with solid, reliable background population data. Following Kassan’s [7] original description, risks of non-haematological malignancies have only been analysed in patient populations identified by hospital discharge registries [9, 22], which are likely to be biased towards more severe cases of pSS. Lymphoma (and malignancy) incidence and prevalence in the background population is subject to continuous change [23, 24], attributable to population dynamics, true changes in SIRs, improved diagnosis and survival rates. Risks in the target cohort must be carefully calculated and compared to age, sex and calendar period adjusted expected risks. Swedish Health Registers, including the Cancer Register [25, 26] and Cause-of-Death Register [27], allow to implement a reliable comparison by linking patient registers to official registers using the Swedish personal identification number [28].

The aim of the present study was to analyse the degree of risk of lymphoproliferative malignancy in a prospectively collected mono-centre pSS cohort, identified in an out-patient clinic setting, taking advantage of the Swedish health system registers allowing exact detection of incident cases of malignancies [25]. Primary objectives were calculation of SIRs for lymphomas and other malignancies and detection of predictors of lymphoma.

PATIENTS AND METHODS
Malmö Sjögren’s Syndrome Register:
Since 1984 patients with pSS were consecutively registered and followed prospectively with intervals of 6 months to 2 years collecting clinical, laboratory and histological data.

Swedish health care registers:
Nationwide population-based mandatory registers for census data, death and cancer incidence, identifying individuals according to the unique national identification number [28], allow for linkage of these registers with each other and local registers such as the Malmö SS Register. The coverage (99%) and quality of information has been found to be excellent [25, 29].

Study cohort and observation time:
The study cohort consisted of all 507 patients included in the pSS register up to December 2002, who lived in Sweden and fulfilled either the Copenhagen [30], the 1993 European [31] or the American-European Consensus Criteria (AECC) [1] (n=286) for pSS. None of the patients had known Hepatitis C, HIV, Sarcoidosis or preexisting lymphoma. The observation period covered the time from 1984 until December 31, 2002, up to which information from the National Death and Cancer Register were available. Thus the individual observation time was from the time-point of diagnosing pSS until the first malignancy, death or the closure date of December 31, 2002, whichever appeared first. Four AECC and 6 non-AECC patients could not be matched with the national registries, thus being lost to follow-up. The individual
observation time was in median 8 years (1 month to 19 years). The total observation time was
2464 years in AECC SS and 1840 in the non-AECC sicca patients.

Representativeness of the study cohort:
The majority of the patients lived in Malmö and surroundings. Our cohort covers about 20%
to 30% of those expected to fulfil the AECC in our region including those with subclinical
disease [12].

Verification of lymphoma types:
The type of the lymphoproliferative malignancies was re-classified according to the 2001
WHO classification for Tumours of Haematopoietic and Lymphoid Tissues [32] by one of the
authors (OL).

Variables in the predictor analysis (only AECC-group, n=286):
As possible predictor variables for lymphoma development we included salivary gland
swelling, purpura or skin vasculitis, autoantibodies (ANA, anti-SSA/Ro, anti-SSB/La, IgM-RF),
salivary gland biopsy, serum immunoglobulins, levels of complement factors C3 and C4
and lymphocyte subtype abnormalities, especially absolute or relative CD4+ T-
lymphocytopenia or a low ratio of CD4+/CD8+ T-cells. Normal ranges: IgG: 6.19-14.9 g/l,
IgA: 0.7-3.65 g/l, IgM: 0.39-2.08 g/l, C3: 0.77-1.38g/l, C4: 0.12-0.33g/l, CD4+: 30-50% of
lymphocytes, CD4+ absolute count: 300-2000 cells/µl, CD4+/CD8+ ratio: 0.8-3.0.

Determination of peripheral blood lymphocyte subtype distribution had been performed by
flow cytometry, beginning 1988, as described [17, 33], in 165 (57%) AECC patients. CD4+
T-lymphocytopenia was defined according to the reference limits of our laboratory. Patients
with severe CD4+ T-lymphocytopenia were tested repeatedly to ensure the reliability of the
results and investigated for predisposing conditions. Only CD4+ T-lymphocytopenia without
evidence for drug induction or virus infection was included in the statistical calculations.
Cryoglobulins were not analysed routinely, since cryoglobulinaemia has been shown to be
unusual in Nordic populations [34].

Linkage procedure:
Using the national personal identification number, issued to all permanent residents in
Sweden, the SS register was linked to the National Cancer and Cause-of-Death Registers by
the National Board of Health and Welfare, retrieving all cancer diagnoses, deaths and causes
of death in the study population until December 31, 2002.

Statistics:
Calculation of SIRs:
Expected risks for malignancies were calculated by comparison with the background
population (region of Southern Sweden) matched for age, sex and calendar period. A SIR was
calculated by dividing observed by expected risk. Exact 95% confidence intervals calculated
from binomial distributions were created for the SIRs.
Cancer diagnoses were grouped (for detail see table 2) according to International
Classification of Diseases, 7th Revision (ICD 7). Risk estimates were calculated for the first
malignancy after the pSS diagnosis without latency period.

Predictor analysis:
COX regression analysis with proportional hazards assumption adjusted for age was applied
in order to study the influence of laboratory, clinical and histological findings at the time of
diagnosis on lymphoma incidence. For CD4+ T-lymphocytopenia observation time from the
first available flow cytometry (in all cases before lymphoma development) until lymphoma or
cancelling date was used. The low number of events of lymphoproliferative malignancies (12
patients) did not allow for the use of multivariate analysis. The high prevalence of positive
salivary gland biopsy both in patients without (90%) and those with (100%) lymphoma
makes this variable unsuitable as a predictor. Predictors were used as continuous variables
whenever possible, expressing HRs as risks per 1 standard-deviation change. For complement and immunoglobulins due to partly u-shaped distributions of the risk estimates the results were divided into quartiles, comparing highest and lowest quartiles with the two in between. **Power analysis:**

With the available patient number and events of NHLs compared to expected events our study had an 80% power of detecting a statistically significant increase of the risk of lymphoma by 500% to a SIR of 5.1, within the patient group fulfilling the AECC. The detected SIR and its 95% confidence interval are above this level.

**RESULTS**

**Demographic and basic clinical variables:**

Ninety-two % of the patients were Scandinavian, 90% were women. The disease duration from appearance of the first symptom until diagnosis (estimated by the patient at the first contact) was in median 7 years. Table 1 gives baseline characteristics by patient group.

Age: years (median/range). Biopsy positive: lower lip salivary gland biopsy with a focus score >1. IgG, C3, C4, CD4+, CD8+, CD4/CD8: median (range). ° n-observed (% of available). § % of total lymphocyte count. §§CD4-penia defined as either CD4+ T-cells <300 cells/µl or CD4+ T-cells <30% of total lymphocyte count or CD4/CD8 ratio <0.8. * significantly different from AECC SS without malignancy with p < 0.05, ** significantly different from AECC SS without malignancy with p < 0.01, *** significantly different from AECC SS without malignancy with p < 0.001.
Standardized incidence ratios (SIRs) for lymphomas and solid tumours (Table 2)

In the AECC group 33 tumours were detected during the 2464 years of observation, while 23.21 were expected, resulting in an SIR of 1.42 (95% CI:0.98-2.00). Two of these patients had suffered other malignancies before the diagnosis of pSS. Furthermore prior to their pSS diagnosis 11 patients had diagnosed malignancies, including a chronic myeloic leukaemia, but did not develop malignancies later on. After the pSS diagnosis 2 patients developed more than 1 malignancy: one patient developed a myeloma after a lymphoma, one patient renal cancer after a breast cancer. At least 4 patients later developing lymphoproliferative neoplasms had skin cancers previously, (two cases basal-cell cancers, one squamous-cell cancer and in the fourth a combination of both types), detected by re-reading the lymphoma patients’ case records (reporting of basal-cell carcinomas was not mandatory before 2003).

For non-AECC patients the SIR for all cancers was 0.77 (0.41-1.32), no lymphoproliferative diseases were observed after pSS diagnosis.

In 286 AECC patients with a median observation time of 7 years, 11 NHLs, and 1 myeloma occurred as first malignancy after pSS diagnosis. The expected number for NHL was 0.79, resulting in a SIR of 15.57 (95% CI 7.77–27.85, p < 0.0001). The patient registered as myeloma in the cancer register had simultaneously a diffuse large B-cell lymphoma (DLBC) according to several re-evaluations.

Table 2 gives the SIRs for selected malignancies. To summarize, patients with pSS according to AECC have a non-significant increase in total risk of malignancy (point estimate 1.42). There was an excess of 10.2 malignancies, completely attributable to the excess in lymphoma/myeloma. This results in an excess malignancy of 4.2 per 1000 patient years at risk. The risk of lymphoma increased with time after the diagnosis of pSS: During the first 5 years the SIR for NHL was 6.4 (95% CI 1.3-18.7), during year 6 to 10 it was 11.1 (3.0-28.5) and during year 10-15 20.8 (6.8-48.6). The shortest duration between diagnosing pSS and lymphoma was 10 months in a patient with a 10-year history of sicca symptoms prior to pSS diagnosis. The point estimate for risk of pulmonary carcinomas was increased, although the small number makes precision poor: SIR 2.47 (0.67-6.32). The SIR for all non-haematological malignancies in the AECC SS patients was 0.93 (0.59-1.40).

**Lymphoma types after re-evaluation:**
Details of the 12 cases with re-classification of the WHO histopathology of the lymphoma biopsies are shown in table 3. Eleven of 12 patients had B-cell NHLs, (two of them appearing simultaneously with or followed by a myeloma). One patient had a T-cell lymphoma. Seven of the 11 B-cell lymphomas were DLBC lymphomas. This type comprised 58% of all NHLs in our cohort. Only 2 lymphomas (a follicular and a DLBC) were localized to the salivary gland region, but both were interpreted as originating from lymph nodes, in one case within and in the other adjacent to the parotid gland. In one patient with high grade DLBC lymphoma transformation from a MALT lymphoma could not be excluded. One patient had a submandibular pseudolymphoma 18 years before the DLBC lymphoma in a neck lymph gland. Re-evaluation of the tissue from this submandibular gland only revealed a lymphoepithelial lesion.

* evaluated at diagnosing pSS, °developing during the course of disease before lymphoma development, but not present or not analysed at first visit. ND not done, BM = bone marrow. LN = lymph node, ## biopsy in this case contained insufficient glandular tissue for evaluation. §CD4-penia is defined as number of CD4 below 300 cells/µl, % of CD4 below 30, or ratio of CD4/CD8 below 0.8. # + = focus score >1

°This patient had had a pseudolymphoma in a submandibular gland before her pSS was diagnosed (18 years before the large B-cell lymphoma). At reevaluation of the tissue the lymphoepithelial lesion without full-blown malignancy was confirmed.
Survival after lymphoma diagnosis:
Seven of 12 patients with lymphoma/myeloma had died (Table 3). The median survival time for all lymphoma patients was 43 months (low-grade 76, high-grade 31, log rank test: 0.08).

Predictors of lymphoma development: Cox regression analysis within the AECC group (n=286) Table 4:
The strongest predictor of lymphoma was a lowered CD4+/CD8+ T-cell ratio. Eight of 11 patients with available lymphocyte subtyping had a CD4+/CD8+ T-cell ratio of ≤0.8, resulting in a HR of 10.92 (95% CI: 2.80-41.83). The low number of events made multivariate regression analysis impossible, only adjustment for age was performed. Levels of immunoglobulins were not significantly associated with increased risks. Patients later developing lymphoma/myeloma had significantly lower relative numbers of CD4+ T-lymphocytes, increased CD8+ T-lymphocytes and lowered ratio of CD4+/CD8+ (p <0.01, <0.001 and <0.01 respectively) (Table 1). Figure 1 shows Kaplan-Meier plots for the risk of developing NHL/myeloma in patients presenting with or without CD4+ T-lymphocytopenia. The time between the lymphocyte count and the lymphoma was in median 88 months (4-156). Low levels of complement factors C3 and C4 predicted haematological malignancy. Nine of the 12 patients had disorders associated with lymphoma development themselves, such as celiac disease [35], Helicobacter pylori [36], psoriasis [37], autoimmune thyreoiditis [38], skin cancers [39, 40]. Methotrexate, auranofin, ocular (topical) cyclosporine and chloroquine were the only anti-rheumatic drugs used before lymphoma appearance (Table 3).

Table 4. Predictors of lymphoproliferative disease (n=12) within the AECC group (n=286).

The analysis was performed using COX regression with adjustment for age. * HR per 1 standard deviation (SD) increase. CD4+ (%) mean: 43.32, SD: 12.20, CD8+ (%) mean: 28.59, SD: 13.01, CD4+/CD8+ ratio: 1.90, SD: 1.18. ° Due to a u-shaped distribution for the risk of lymphoma, quartiles for C3, C4 and IgG were used, testing the risks for the highest and lowest quartiles versus the two middle ones. For all predictors first ever assessment is used.

**DISCUSSION**

We have performed an analysis of the risk of malignancy in general and lymphoproliferative neoplasms in particular in our prospectively followed cohort of pSS patients. The focus of this study was on patients fulfilling the AECC for pSS [1].

There are mainly 2 new messages:

1) The often cited risk estimate for NHL of 44 fold increase compared with the background population is probably valid only for highly selected patient populations with severe disease, while a lower risk estimate as found in this study (16 fold increase) is probably more representative for an average pSS population. No other malignancies were overrepresented with statistical significance, although the power to detect such deviations was low.

2) Our results show a substantial risk increase for developing lymphoproliferative malignancy in patients with a decreased CD4+/CD8+ T-lymphocyte ratio. No previous longitudinal cohort study has evaluated the significance of T-cell disturbances with respect to outcome in pSS despite the fact that the presence of CD4+ T-lymphocytopenia was described years ago and suggested to be associated with cases of NHL [17]. Earlier proposed risk factors such as hypocomplementaemia and skin vasculitis are confirmed.

Additional interesting observations include the presence of further predisposing factors such as autoimmune thyroiditis, celiac disease, *H pylori* infection, skin cancers or psoriasis, which may deserve increased awareness and intensified search for lymphoma when combined with suspicious clinical or laboratory signs. The significance of these coincidences requires confirmation. However, the high frequency of earlier non-melanoma skin cancers in our

</table>
lymphoma patients is in concordance with several recent reports on increased lymphoma risks in skin cancer patients [39, 40]. Surprisingly, the NHLs in our pSS cohort are in 58% high-grade, diffuse large B-cell (DLBC) lymphomas. In concordance with our previous study on mortality also the present investigation underlines the importance of strict and universally accepted classification criteria, as patients not fulfilling the AECC criteria do not show any increased lymphoma risk in contrast to those who do so.

Strengths of the present study are the strict mono-centre prospective design of the data collection in combination with the highly reliable Swedish general health registers [25]. In addition, the follow-up time of up to 19 years (median 8 years) is relatively long. This seems to be a prerequisite to allow evaluation of long-term severe outcomes such as death or cancer development. When Kirtava 1995 [17] described 6 patients with CD4+ T-lymphocytopenia from our department (follow-up up to 7 years), only 1 had developed lymphoma. In the present study we found that another 2 of these patients had developed a lymphoma. The mean time between diagnosing pSS and the appearance of the lymphoma was in the present study 8 years (1-13 years). The risk of lymphoma increases with follow-up time, exemplified by the highest SIR of >20 being observed in those followed more than 10 years.

CD4+ T-lymphocytopenia has been described in association with and preexisting before NHLs [41-44]. In our study all the risk calculations were performed using the first available CD4+ T-cell analysis, most often performed at or shortly after the time of diagnosing pSS, and always before the lymphoma detection (Table 3), which excludes the possibility of a lymphoma induced CD4+ T-lymphocytopenia. We have to acknowledge the lack of systematic cryoglobulin analysis in our cohort as an important drawback. The assumption that cryoglobulinaemia is rare in Swedish pSS patients [34] needs to be revised in the light of the new classification criteria.

Our study differs from previous studies in several important aspects. The lymphoma incidence was lower than in Kassan’s original description, which however, as the authors themselves point out, may not be generalized to other populations less prone to selection bias [7]. Furthermore their study had slightly less precision, being based on only 7 (4 primary SS lymphoma) cases. The described histiocytic diffuse and Lennert’s lymphomas in 6 of 7 cases would correspond to high-grade DLBC and T-cell lymphomas in the present WHO classification. This is in accordance with our cases with predominantly high-grade DLBC. In contrast, two other case series have documented a predominance of low-grade lymphomas, quite often in salivary glands and of MALT type [10, 45], while another study did not find any MALT lymphomas among 4 SS associated NHLs [8]. Only one of our cases could possibly be classified as MALT lymphoma. Our approach with linkage to the validated national cancer register excludes any major detection bias, which may operate when cases are identified in routine clinical settings. Transformation from earlier MALT lymphoma into DLBC lymphoma can however not be excluded. Survival after lymphoma was comparable with previous reports when comparing groups of high- and low-grade lymphomas separately [10].

The lymphoma types found in our study are similar to those found in Swedish RA cohorts [46]. Also in SLE, the associated lymphomas are predominantly of the DLBC type [47]. The reported increase in risk with disease duration is similar to studies in RA, but in contrast to studies in SLE, where the highest risk is observed within the first 5 years after diagnosis [47]. In RA high disease activity is the most important predictive factor for lymphoma [48]. Disease activity is difficult to assess in pSS. Correlation between extraglandular disease and
CD4+ T-lymphocytopenia due to apoptosis was described in pSS [19]. It seems conceivable that a longstanding deficiency in immune surveillance finally allows malignant transformation in antigen-stimulated proliferating B-cells. The causes of CD4+ T-lymphocyte depletion or disturbed balance between CD4+ and CD8+ T-cells are unknown. Anti-CD4+ antibodies have been documented in pSS patients without correlation to the level of CD4+ T-cells [49]. Virus infections are typical causes of lymphopenia, and HIV infection is the prototype of virus-induced CD4+ T-lymphocytopenia, associated with lymphoma development [50]. Hepatitis C [51] and EBV [52] are viruses associated with lymphoma development and autoimmunity. Coxsackie B virus was recently proposed as an etiologic factor in pSS [53, 54], but its potential to induce cytopenia has not been studied. CD4+ T cells and subsets of the CD4+ T-lymphocytes are important in tumour immunity [55]. To what extent the different predictors for lymphoma development, such as cryoglobulinemia, hypocomplementemia, B-cell activation and CD4+ T-cell depletion have a shared etiology or represent different aspects of risk needs to be elucidated.

In summary our results suggest that CD4+ T-lymphocytopenia is a useful clinical predictor, which possibly is of crucial importance in the sequence of events leading to lymphoma development in pSS patients. Previously proposed risk factors, such as hypocomplementemia and skin vasculitis could be confirmed, while aggressive types of lymphomas were frequent in our cohort. The overall lymphoma risk was lower than earlier proposed, but increased with longer disease duration.

ACKNOWLEDGMENTS
We thank biostatistician Jan Åke Nilsson (Malmö University Hospital) for the professional support in performing the statistical analyses and Dr Anna Bladström (Southern Swedish Cancer Registry) for calculating cancer specific SIRs. This study was supported by the Swedish Rheumatism Association and the Skane County Council’s Research and Development Foundation and the European BIOMED concerted action BMH4-96-0595.
